

# Source and Accuracy of Estimates for *Income in the United States: 2002*

---

## SOURCES OF DATA

Most estimates in this report come from data obtained in March of years 1968 through 2003 in the Current Population Survey (CPS). The survey is conducted every month, although this report uses only March CPS data for its estimates. The March CPS uses two sets of questions, the basic CPS and the Annual Social and Economic Supplement (ASEC).

Data was used from various sources in developing alternative measures of income for 2002. Specifically, data from the American Housing Survey (AHS), the Income Survey Development Program (ISDP), and the Internal Revenue Service (IRS) with CPS data to create simulations of taxes paid, number of tax filing units, adjusted gross income, and other tax characteristics were combined for the March 2003 CPS.

In addition, this report uses the *State Tax Handbook* from the Commerce Clearing House as an information source for tax data. For noncash valuation estimates, this report uses data from the U.S. Department of Agriculture (USDA), the Health Care Financing Administration (HCFA), and the Department of Housing and Urban Development (HUD).

A description of the sources of data we used to derive these estimates follows. Except for the CPS, these descriptions are brief. See Current Population Reports, Series P60-186RD, *Measuring the Effect of Benefits and Taxes on Income and Poverty: 1992*, and publications on the appropriate surveys for more details.

**American Housing Survey.** Housing data was collected for the Department of Housing and Urban Development. The population covered by the sample for the AHS (called the Annual Housing Survey before 1984) includes all housing units in the United States. For a more detailed description of the sample design, see the report Current Housing Reports, Series H150-89, *The American Housing Survey for the United States in 1989*, U.S. Department of Commerce.

The AHS is no longer conducted in even-numbered years, so the property tax estimates in this report are based on the 1995 AHS. Also, for the noncash estimates, the 1985 AHS data was used in a model to estimate the

value of public housing. For more details on the AHS model used to estimate public and subsidized housing values, please see Appendix B of Current Population Reports, Series P60-186RD, *Measuring the Effect of Benefits and Taxes on Income and Poverty: 1992*.

**Income Survey Development Program.** The ISDP was the research and development phase for the Survey of Income and Program Participation (SIPP). The ISDP was used to examine and resolve design, operational, and technical issues for SIPP. The household sample for the 1979 ISDP was a nationwide, multiple-frame sample. The majority of sample households in the ISDP came from addresses contacted in the 1976 Survey of Income and Education. Statisticians selected the remainder of sample households from a reserve file of sample cases maintained by the Census Bureau. For a more detailed description of this sample design, see the report Wage and Salary Data From the Income Survey Development Program: 1979 (Preliminary Data From Interview Period One), Current Population Reports, Special Studies, Series P-23, No. 118.

**Internal Revenue Service Data.** Much of the IRS data in this report came from the Statistics of Income (SOI) series, in particular the SOI Bulletin Individual Income Tax Returns, Preliminary Data: 2001, spring 2003. This report, based on a sample drawn from all tax returns filed in 2002, presents information on taxpayers' incomes, exemptions, deductions, credits, and taxes.

**Data From Other Sources.** The State Tax Handbook, October 1, 1991, from the Commerce Clearing House, includes information on state tax systems. These data were updated to reflect changes in state income tax rates.

Much of the data on cash and noncash benefits are from administrative records. Values of school lunches and food stamps are from USDA unpublished data. Medicaid and Medicare data come from HCFA unpublished records. Also, USDA and HUD data are used to compute Medicaid and Medicare values. For more details, see Appendix B of Current Population Reports, Series P60-186RD, *Measuring the Effect of Benefits and Taxes on Income and Poverty: 1992*.

Table 1.  
**Description of the March Current Population Survey**

Time period	Number of sample areas	Housing units eligible <sup>1</sup>	
		Interviewed	Not interviewed
2001 to 2003 .....	754	55,500	4,500
1996 to 2000 .....	754	46,800	3,200
1995 .....	792	56,700	3,300
1990 to 1994 .....	729	57,400	2,600
1989 .....	729	53,600	2,500
1986 to 1988 .....	729	57,000	2,500
1985 .....	<sup>2</sup> 629/729	57,000	2,500
1982 to 1984 .....	629	59,000	2,500
1980 to 1981 .....	629	65,500	3,000
1977 to 1979 .....	614	55,000	3,000
1973 to 1976 .....	461	46,500	2,500
1972 .....	449	45,000	2,000
1968 to 1971 .....	449	48,000	2,000

<sup>1</sup>Excludes about 12,500 households added due to the SCHIP sample expansion, 1,300 of which are not interviewed. (See "Annual Social and Economic Supplement.")

<sup>2</sup>The Census Bureau redesigned the CPS following the 1980 Decennial Census of Population and Housing. During phase-in of the new design, housing units from the new and old designs were in the sample.

Source: U.S. Census Bureau, Demographic Statistical Methods Division.

**Basic CPS.** The monthly CPS collects primarily labor force data about the civilian noninstitutional population. Interviewers ask questions concerning labor force participation about each member 15 years old and over in every sample household.

**Annual Social and Economic Supplement.** For the March CPS, interviewers ask additional questions in March 2003 about money income received during the previous calendar year.

**Basic CPS Sample Design.** The present monthly CPS sample was selected from the 1990 Decennial Census files with coverage in all 50 states and the District of Columbia. The sample is continually updated to account for new residential construction. To obtain the sample, the United States was divided into 2,007 geographic areas. In most states, a geographic area consisted of a county or several contiguous counties. In some areas of New England and Hawaii, minor civil divisions are used instead of counties. These 2,007 geographic areas were then grouped into 754 strata, and one geographic area was selected from each stratum.

About 60,000 occupied households are eligible for interview every month out of the 754 strata. Interviewers are unable to obtain interviews at about 4,500 of these units. This occurs when the occupants are not found at home after repeated calls or are unavailable for some other reason.

The number of households that are eligible for interview in the basic CPS increased from 50,000 to 60,000 in July

of 2001. With the increase in eligible households, the number of units where interviewers were unable to obtain an interview increased from 3,200 to 4,500.

**The Annual Social and Economic Supplement Sample Design.** To obtain more reliable data for certain minority groups, the ASEC sample includes 21,000 eligible housing units in addition to the 60,000 eligible housing units from the basic CPS. The 21,000 eligible housing units include Hispanic households, non-Hispanic minority households, and non-Hispanic White households with children 18 years or younger. These additional eligible households were identified for sample from previous months and the following April.

Most of the ASEC data collection occurs in March, but because of the sample expansion, some data collection occurs in February and April.

**Sample Redesign.** Since the introduction of the CPS, the Census Bureau has redesigned the CPS sample several times. These redesigns have improved the quality and accuracy of the data and have satisfied changing data needs. The most recent changes were phased in and implementation was completed in 1995.

Table 1 summarizes changes in the CPS designs for the years for which data appear in this report.

**Estimation Procedure.** This survey's estimation procedure adjusts weighted sample results to agree with independent estimates of the civilian noninstitutional population of the United States by age, sex, race,

---

Hispanic/non-Hispanic ancestry, and state of residence. The adjusted estimate is called the post-stratification ratio estimate. The independent estimates are calculated based on information from three primary sources:

- The 2000 Decennial Census of Population and Housing.
- Statistics on births, deaths, immigration, and emigration.
- Statistics on the size of the armed forces.

The estimation procedure for the ASEC supplement included a further adjustment so husband and wife of a household received the same weight. The independent population estimates include some, but not all, unauthorized migrants.

## ACCURACY OF THE ESTIMATES

A sample survey estimate has two types of error: sampling and nonsampling. The accuracy of an estimate depends on both types of error. The nature of the sampling error is known given the survey design. The full extent of the nonsampling error, however, is unknown.

**Sampling Error.** Since the CPS estimates come from a sample, they may differ from figures from a complete census using the same questionnaires, instructions, and enumerators. This possible variation in the estimates due to sampling error is known as “sampling variability.”

**Nonsampling Error.** All other sources of error in the survey estimates are collectively called nonsampling error. Sources of nonsampling error include the following:

- Inability to obtain information about all sample cases (nonresponse).
- Definitional difficulties.
- Differences in the interpretation of questions.
- Respondent inability or unwillingness to provide correct information.
- Respondent inability to recall information.
- Errors made in data collection, such as in recording or coding the data.
- Errors made in processing the data.
- Errors made in estimating values for missing data.
- Failure to represent all units with the sample (undercoverage).

Answers to questions about money income often depend on the memory or knowledge of one person in a household. Recall problems can cause underestimates of income in survey data, because it is easy to forget minor or irregular sources of income. Respondents may also misunderstand what the Census Bureau considers money income or may simply be unwilling to answer these questions correctly because the questions are considered too personal. See Appendix C, Current Population Reports, Series P60-184, *Money Income of Households, Families, and Persons in the United States: 1992* for more details.

**Undercoverage.** The concept of coverage in the survey sampling process is the extent to which the total population that could be selected for sample “covers” the survey’s target population. CPS undercoverage results from missed housing units and missed people within sample households. Overall CPS undercoverage is estimated to be about 11 percent. CPS undercoverage varies with age, sex, race, and ancestry. Generally, undercoverage is larger for males than for females and larger for Blacks and other races combined than for Whites.

The Current Population Survey weighting procedure uses ratio estimation whereby sample estimates are adjusted to independent estimates of the national population by age, race, sex, and Hispanic ancestry. This weighting partially corrects for bias due to undercoverage, but biases may still be present when people who are missed by the survey differ from those interviewed in ways other than age, race, sex, and Hispanic ancestry. How this weighting procedure affects other variables in the survey is not precisely known. All of these considerations affect comparisons across different surveys or data sources.

A common measure of survey coverage is the coverage ratio, the estimated population before post-stratification divided by the independent population control. Table 2 shows CPS coverage ratios for age-sex-race-ancestry groups for a typical month. The CPS coverage ratios can exhibit some variability from month to month. Other Census Bureau household surveys experience similar coverage.

**Comparability of Data.** Data obtained from the CPS and other sources are not entirely comparable. This results from differences in interviewer training and experience and in differing survey processes. This is an example of nonsampling variability not reflected in

Table 2.  
**March CPS Coverage Ratios**

Age group	Totals			White only		Black only		Residual race		Hispanic <sup>1</sup>

the standard errors. Therefore, caution should be used when comparing results from different sources.

A number of changes were made in data collection and estimation procedures beginning with the January 1994 CPS. The major change was the use of a new questionnaire. The questionnaire was redesigned to measure the official labor force concepts more precisely, to expand the amount of data available, to implement several definitional changes, and to adapt to a computer-assisted interviewing environment. The Annual Social and Economic supplemental income questions were also modified for adaptation to computer-assisted interviewing, although there were no changes in definitions and concepts. See Appendix C, P-60, No. 188 on "Conversion to a Computer Assisted Questionnaire" for a description of these changes and the effect they had on the data. Due to these and other changes, one should use caution when comparing estimates from data collected before 1994 with estimates from data collected in 1994 and later.

Caution should also be used when comparing CPS estimates in this report, which reflect 2000 census-based population controls, with estimates from March 1994-2001, which reflect 1990 census-based population controls. Estimates from previous years reflect the latest available census-based population controls. Although this change in population controls had relatively little impact on summary measures, such as means, medians, and percentage distributions, it did have a significant impact on levels. For example, use of 2000 based population controls results in about a 1 percent increase from the 1990-based population controls in the civilian noninstitutional population and in the number of families and households. Thus,

estimates of levels for data collected in 2002 and later years will differ from those for earlier years by more than what could be attributed to actual changes in the population. These differences could be disproportionately greater for certain subpopulation groups than for the total population.

Caution should also be used when comparing Hispanic estimates over time. No independent population control totals for people of Hispanic ancestry were used before 1985.

Based on the results of each decennial census, the Census Bureau gradually introduces a new sample design for the CPS. During this phase-in period, CPS data are collected from sample designs based on different censuses. While most CPS estimates were unaffected by this mixed sample, geographic estimates are subject to greater error and variability. Users should exercise caution when comparing estimates across years for metropolitan/nonmetropolitan categories. For more information, see Appendix C, Current Population Reports, Series P60-193, *Money Income in the United States: 1995* (With Separate Data on Valuation of Noncash Benefits).

**A Nonsampling Error Warning.** Since the full extent of the nonsampling error is unknown, one should be particularly careful when interpreting results based on small differences between estimates. Even a small amount of nonsampling error can cause a borderline difference to appear significant or not, thus distorting a seemingly valid hypothesis test. Caution should also be used when interpreting results based

<sup>1</sup> Subpopulation.

---

on a relatively small number of cases. Summary measures probably do not reveal useful information when computed on a base<sup>1</sup> smaller than 75,000.

For additional information on nonsampling error including the possible impact on CPS data when known, refer to

- Statistical Policy Working Paper 3, *An Error Profile: Employment as Measured by the Current Population Survey*, Office of Federal Statistical Policy and Standards, U.S. Department of Commerce, 1978.
- Technical Paper 63RV, *The Current Population Survey: Design and Methodology*, U.S. Census Bureau, U.S. Department of Commerce, 2002.

**Estimation of Median Incomes.** The methodology for computing median income has changed over the past few years. Medians were computed using either Pareto interpolation or linear interpolation. Currently, linear interpolation is used to estimate all medians. Pareto interpolation assumes a decreasing density of population within an income interval, whereas, linear interpolation assumes a constant density of population within an income interval. Estimates of median income for 1979 through 1987 and associated standard errors were calculated using Pareto interpolation if the estimate was larger than \$20,000 for people or \$40,000 for families and households. This is because the width of the income interval containing the estimate is greater than \$2,500.

Estimates of median income for 1976, 1977, and 1978 and associated standard errors were calculated using Pareto interpolation if the estimate was larger than \$12,000 for people or \$18,000 for families and households. This is because the width of the income interval containing the estimate is greater than \$1,000. All other estimates of median income and associated standard errors for 1976 through 2001 and almost all of the estimates of median income and associated standard errors for 1975 and earlier were calculated using linear interpolation.

Thus, use caution when comparing median incomes above \$12,000 for people or \$18,000 for families and households for different years. Median incomes below those levels are more comparable from year to year since they have always been calculated using linear interpolation. For an indication of the comparability of medians calculated using Pareto interpolation with medians calculated using linear interpolation, see Series P-60, No. 114, *Money Income in 1976 of Families and Persons in the United States*.

**Standard Errors and Their Use.** The sample estimate and its standard error enable one to construct a confidence interval. A confidence interval is a range that would include the average result of all possible samples with a known probability. For example, if all possible samples were surveyed under essentially the same general conditions and the same sample design, and if an estimate and its standard error were calculated from each sample, then approximately 90 percent of the intervals from 1.645 standard errors below the estimate to 1.645 standard errors above the estimate would include the average result of all possible samples.

A particular confidence interval may or may not contain the average estimate derived from all possible samples. However, one can say with specified confidence that the interval includes the average estimate calculated from all possible samples.

Standard errors may be used to perform hypothesis testing. This is a procedure for distinguishing between population parameters using sample estimates. The most common type of hypothesis is that two population parameters are different. An example of this would be comparing the median annual income of Black families with the median annual income of White non-Hispanic families.

Tests may be performed at various levels of significance. A significance level is the probability of concluding that the characteristics are different when, in fact, they are the same. For example, to conclude that two parameters are different at the 0.10 level of significance, the absolute value of the estimated difference between characteristics must be greater than or equal to 1.645 times the standard error of the difference.

The Census Bureau uses 90-percent confidence intervals and 0.10 levels of significance to determine statistical validity. Consult standard statistical textbooks for alternative criteria.

**Estimating Standard Errors.** To estimate the standard error of a CPS estimate, the Census Bureau uses replicated variance estimation methods. These methods primarily measure the magnitude of sampling error. However, they do measure some effects of nonsampling error as well. They do not measure systematic biases in the data due to nonsampling error. Bias is the average over all possible samples of the differences between the sample estimates and the true value.

**Generalized Variance Parameters.** Consider all the possible estimates of characteristics of the population that are of interest to data users. Now consider all the

Table 3.

Notes: To obtain parameters prior to 2002, multiply by the appropriate factor in Table 4.

For nonmetropolitan residence categories multiply the a and b parameters by 1.5.

For foreign-born and noncitizen characteristics for Total and White, multiply the a and b parameters by 1.3. No adjustment is necessary for foreign-born and noncitizen characteristics for Blacks and Hispanics.

For regional estimates, multiply the a and b parameters by 0.90, 0.93, 1.14, and 1.14 for Northeast, Midwest, South, and West, respectively.

Source: U.S. Census Bureau, Demographic Statistical Methods Division.

subpopulations such as racial groups, age ranges, etc. Finally, consider every possible comparison or ratio combination. The list would be completely unmanageable. Similarly, a list of standard errors to go with every estimate would be unmanageable.

Through experimentation, we have found that certain groups of estimates have similar relationships between their variances and expected values. We provide a generalized method for calculating standard errors for any of the characteristics of the population of interest. The generalized method uses generalized variance parameters for groups of estimates. Table 3 has CPS standard error parameters for income and various non-income characteristics. Table 4 provides factors to approximate CPS standard error parameters for estimates before 2001. Table 5 provides CPS Hispanic

parameters for estimates before 1984. Table 6 provides CPS parameters for income and various non-income characteristics for Asian and Pacific Islanders and American Indian and Alaskan Natives. Table 7 contains the year-to-year CPS correlation coefficients for income characteristics.

**Standard Errors of Estimated Numbers.** The approximate standard error,  $s_x$ , of an estimated number shown in this report can be obtained using the formula

$$s_x = \sqrt{ax^2 + bx} \quad (1)$$

Here  $x$  is the size of the estimate and  $a$  and  $b$  are the parameters in Table 3 or 6 associated with the particular type of characteristic. When calculating standard errors for numbers from cross-tabulations involving

different characteristics, use the set of parameters for the characteristic which will give the largest standard error.

*Illustration.* There were 75,596,000 family households in 2002. Use the appropriate parameters from Table 3 and formula (1) to get

Estimate, x	75,596,000
a parameter	-0.000004
b parameter	1,052
Standard error	238,000
90% conf. int.	75,204,000 to 75,988,000

The standard error is calculated as

$$s_x = \sqrt{-0.000004 \times 75,596,000^2 + 1,052 \times 75,596,000} = 238,000$$

The 90-percent confidence interval for the estimated number of family households in 2002 is calculated as 75,596,000 ± 1.645 × 238,000.

A conclusion that the average estimate derived from all possible samples lies within a range computed in this way would be correct for roughly 90 percent of all possible samples.

**Standard Errors of Estimated Percentages.** The reliability of an estimated percentage, computed using

sample data from both numerator and denominator, depends on the size of the percentage and its base. Estimated percentages are relatively more reliable than the corresponding estimates of the numerators of the percentages, particularly if the percentages are 50 percent or more. When the numerator and denominator of the percentage are in different categories, use the parameter from Table 3 or 6 indicated by the numerator.

The approximate standard error,  $s_{x,p}$ , of an estimated percentage can be obtained using the formula

$$s_{x,p} = \sqrt{\frac{b}{x} p (100 - p)} \quad (2)$$

Here  $x$  is the total number of people, families, households, or unrelated individuals in the base of the percentage,  $p$  is the percentage ( $0 \leq p \leq 100$ ), and  $b$  is the parameter in Table 3 or 6 associated with the characteristic in the numerator of the percentage.

*Illustration.* There were 13,620,000 or 18.0 percent of the 75,596,000 family households maintained by female householders with no husband present. Use the appropriate parameter from Table 3 and formula (2) to get

Estimate, $p$	18.0
Base, $x$	75,596,000
$b$ parameter	1,052
Standard error	0.14
90% conf. int.	17.8 to 18.2

The standard error is calculated as

$$s_{x,p} = \sqrt{\frac{1,052}{74,386,000} (17.7)(100 - 17.7)} = 0.14$$

The 90-percent confidence interval for the estimated percentage of family households that were maintained by female householders with no husband present is calculated as  $18.0 \pm 1.645 \times 0.14$ .

**Standard Error of a Difference.** The standard error of the difference between two sample estimates is approximately equal to

$$s_{x-y} = \sqrt{s_x^2 + s_y^2 - 2rs_x s_y} \quad (3)$$

where  $s_x$  and  $s_y$  are the standard errors of the estimates,  $x$  and  $y$ . The estimates can be numbers, percentages, ratios, etc. Table 7 contains the correlation coefficient,  $r$ , for year-to-year comparisons for CPS income estimates of numbers and proportions. This will represent the actual standard error quite accurately for the difference between estimates of the same characteristic in two different areas, or for the difference between separate and uncorrelated characteristics in the same area. However, if there is a high positive (negative) correlation between the two characteristics, the formula will overestimate (underestimate) the true standard error.

*Illustration.* The median earnings of all male full-time, year-round workers in 2002,  $x$ , was \$39,429 and the median earnings of all female full-time, year-round workers in 2002,  $y$ , was \$30,203. The apparent difference between the median income of males and females in 2002 was \$9,226. The approximate standard errors,  $s_x$  and  $s_y$ , are \$244 and \$80, respectively. Use formula (3) with  $r = 0$  to get

	<b>x</b>	<b>y</b>	<b>difference</b>
Estimate	\$39,429	\$30,203	\$9,226
Standard error	\$244	\$80	\$257
90% conf. int.	\$39,028	\$30,071	\$8,803
	to	to	to
	\$39,830	\$30,335	\$9,649

The standard error of the difference is calculated as

$$s_{x-y} = \sqrt{(244)^2 + (80)^2} = 257$$

The 90-percent confidence interval for the estimated difference between the median income of male and female full-time, year-round workers in 2002 is calculated as  $\$9,226 \pm 1.645 \times \$257$ . Because this interval does not contain zero, we can conclude with 90-percent confidence that the median income of male full-time, year-round workers in 2002 was larger than the median income of female full-time, year-round workers in 2002.

**Standard Error of a Ratio.** Certain estimates may be calculated as the ratio of two numbers. Compute the standard error of a ratio,  $x/y$ , using

$$s_{x/y} = \frac{x}{y} \sqrt{\left(\frac{s_x}{x}\right)^2 + \left(\frac{s_y}{y}\right)^2 - 2r \frac{s_x s_y}{xy}} \quad (4)$$

Calculate the standard error of the numerator,  $s_x$ , and that of the denominator,  $s_y$ , using formulas described earlier. In formula (4),  $r$  represents the correlation between the numerator and the denominator of the estimate. For one type of ratio, the denominator is a count of families or households and the numerator is a count of people in those families or households with a certain characteristic. If there is at least one person with the characteristic in every family or household, use 0.7 as an estimate of  $r$ . An example of this type is the mean number of children per family with children. For all other types of ratios,  $r$  is assumed to be zero. If  $r$  is actually positive (negative), then this procedure will provide an overestimate (underestimate) of the standard error of the ratio. Examples of this type are the mean number of children per family and the family poverty rate.

**NOTE:** For estimates expressed as the ratio of  $x$  per 100  $y$  or  $x$  per 1,000  $y$ , multiply formula (4) by 100 or 1,000, respectively, to obtain the standard error.

*Illustration.* The median earnings for full-time, year round female workers in 2002,  $x$ , was \$30,203 and the median earnings for full-time, year-round male workers in 2002,  $y$ , was \$39,429. The ratio of the median earnings is 0.77. The approximate standard

errors,  $s_x$  and  $s_y$ , are \$80 and \$244, respectively. Using formula (4) with  $r = 0$  to get

	<b>x</b>	<b>y</b>	<b>ratio</b>
Estimate	\$30,203	\$39,429	0.77
Standard error	\$80	\$244	0.0052
90% conf. int.	\$30,071	\$39,028	0.76
	to	to	to
	\$30,335	\$39,830	0.78

The standard error is calculated as

$$s_{x/y} = \frac{30,203}{39,429} \sqrt{\left(\frac{80}{30,203}\right)^2 + \left(\frac{244}{39,429}\right)^2} = 0.0052$$

The 90-percent confidence interval for the ratio of the median earnings for full-time, year-round female workers to the median earnings for full-time, year-round male workers is calculated as  $0.77 \pm 1.645 \times 0.0052$ .

**Standard Errors of Other Estimates.** This report provides standard errors for most estimates in the respective tables, or includes a formula showing how to calculate them. For information on calculating other standard errors, contact Aneesah Stephenson at e-mail address: [dsmd.source.and.accuracy@census.gov](mailto:dsmd.source.and.accuracy@census.gov).
